Kottwitz MU, Meier LL, Jacobshagen N, Kälin W, Elfering A, Hennig J, Semmer NK. Illegitimate tasks associated with higher cortisol levels among male employees when subjective health is relatively low: an intra-individual analysis. *Scand J Work Environ Health*. 2013;39(3):310–318. doi:10.5271/sjweh.3334

Objectives Illegitimate tasks refer to tasks that do not conform to what can appropriately be expected from an employee. Violating role expectations, they constitute “identity-stressors”, as one’s professional role tends to become part of one’s identity. The current study investigated the impact of illegitimate tasks on salivary cortisol. We analyzed data on an intra-individual level, that is, by examining fluctuations in illegitimate tasks and cortisol within individuals. Furthermore, we investigated the moderating role of perceived health, expecting that illegitimate tasks evoke stronger reactions when perceived health is relatively poor.

Methods Illegitimate tasks, salivary cortisol, and perceived health were assessed in each of three waves (time lag: 6 months) in a sample of 104 male employees. Data were analyzed by multilevel analysis using group mean centering.

Results Controlling for social stressors, work interruptions, and emotional stability, the experience of more illegitimate tasks was associated with increased cortisol release if personal health resources were low compared to one’s mean value of perceived health. Results cannot be explained by inter-individual differences.

Conclusions This is the first study showing that illegitimate tasks predict a biological indicator of stress, thus confirming and extending previous research on illegitimate tasks. The moderating role of perceived health confirms its importance as a personal resource, implying augmented vulnerability when perceived health is below its usual value. It is plausible to assume that increased stress reactions due to relatively poor health may further weaken available personal resources. Both avoiding illegitimate tasks and restoring personal health seem to be crucial.

Key terms interaction; multilevel modeling; psychophysiology; within-person design; work stress.

Social roles, including professional roles, often become part of people’s identity (1–3), and thus, the self (1, 4). People typically strive for maintaining a positive identity (1, 5, 6); therefore, affirming one’s role identity (eg, by being successful in a task) is an important source of pride. Conversely, threats to one’s role identity are likely to induce stress (3, 7, 8). In line with such reasoning, Thoits (9) suggested the term “identity-relevant stressors”. Building on these considerations, Semmer et al (10) introduced “illegitimate tasks” as a new stressor concept. Illegitimate tasks are tasks that violate norms about what an employee can legitimately be expected to do. The (perceived) illegitimacy may derive from (i) the

perception that a task does not conform to an employee’s professional role, such as when experienced employees are asked to do a novice’s work, or (ii) the perception that a task is unnecessary, such as having to document information that no one will ever use (11–13). Semmer et al (10) argue that illegitimate tasks do not respect the focal person’s professional identity and therefore constitute an offense to the self.

Illegitimate tasks may be seen as a relatively stable (“chronic”) construct, which makes sense to the degree that different jobs are characterized by different levels of illegitimate tasks in general. At the same time, however, the level of illegitimate tasks may well fluctuate

around this general level, and thus be higher or lower at certain times.

Previous research (11, 13) has investigated illegitimate tasks in a chronic sense, showing that participants with higher levels of illegitimate tasks report poorer subjective well-being (eg, lower job satisfaction; more feelings of resentment towards one's organization (13) as well as more counterproductive work behavior (11); thus, these studies investigated inter-individual differences. So far, however, no studies have investigated illegitimate tasks on an occasion-specific level, analyzing changes in well-being and health within individuals over time, thus complementing the existing inter-individual analyses with *intra*-individual analyses. Furthermore, existing studies relied on self-report measures for assessing both stressors and outcomes, which implies the danger of inflated effects due to common method variance [(14) but see also (15, 16)]. Finally, existing research has focused on main effects of illegitimate tasks. However, the effects of illegitimate tasks (as well as of other stressors) may not be uniform across people, and across occasions within a person. There may be differences in vulnerability between people, for instance in that people with poor health [eg, as indicated by back pain (17) or high allostatic load (18)] or certain personality characteristics [eg, low internal locus of control (19)] may be especially vulnerable. In an analogous way, *intra*-individual shifts in such variables over time, such as relatively poor health of an individual as compared to people's typical health status, may indicate especially vulnerable periods (20).

The present study extends existing research by (i) analyzing the association of *intra*-individual changes in illegitimate demands with *intra*-individual changes in the stress response, (ii) employing a biological indicator of the stress response, and (iii) considering the impact of illegitimate tasks in relation to differential vulnerability periods, characterized by comparatively high versus low self-reported health.

Cortisol has frequently been used as a biological stress indicator. The hypothalamic-pituitary-adrenal (HPA) axis is part of the neuro-endocrine stress response, with cortisol as its central messenger. Among healthy persons, cortisol usually displays a diurnal rhythm, with values highest in the morning and lowest in the evening. This pattern has been found to change under conditions of stress, both chronic and acute. Increased release of cortisol has been demonstrated as a response to acute stress in laboratory settings (21); however, the results of field studies have been inconclusive (22). More specifically, both increased and decreased cortisol levels have been found (23). This inconclusiveness seems to be due to several factors. First, there are large inter-individual differences in cortisol reactions (24). According to Kudielka et al (25), the majority of stud-

ies investigating *intra*-individual effects by repeated assessments of cortisol and time-varying variables found positive associations between momentary stress and salivary cortisol. Based on this evidence, we expect higher levels of cortisol when people face high illegitimate demands, because we examined *intra*-individual changes (ie, changes within a person) in illegitimate tasks as predictors of *intra*-individual changes in cortisol over time. Second, the timing of the measurement is crucial. Lower levels of cortisol due to stress have typically been found in morning measures. By contrast, afternoon and evening measures are often higher [even in studies that found lower morning values (23)]. Therefore, we assume that cortisol levels at noon also show a tendency towards higher levels. Third, the difference between acute and ongoing versus distant stressors is important. If stressful experiences (typically traumatic experiences in this type of research) had occurred sometime before measures were taken, morning levels tended to be lower; by contrast, if stressors were still present (eg, unemployment), levels (including morning and afternoon levels) tended to be higher (23). Cortisol measures and illegitimate stressors reported at the same measurement occasion imply that illegitimate stressors are still present when cortisol is assessed. Therefore, higher, rather than lower, values of cortisol seem likely. Fourth, the nature of the stressors is important. Specifically, stressful situations that involve a social-evaluative threat tend to evoke a heightened cortisol response (23, 26). Illegitimate tasks are postulated to pose a threat to the self (12), which induces us to expect higher cortisol levels to be associated with higher illegitimate stressors. Each of the four factors – *intra*-individual differences, timing of measurement, distance to stressors, and the nature of the stressors – favors a heightened cortisol response in our study. We therefore hypothesize that *intra*-individual levels of illegitimate tasks will be positively related to *intra*-individual workday cortisol release (hypothesis 1).

The preceding considerations refer to main effects; however, it seems likely that the cortisol response is qualified by moderating variables (27). The general state of the organism in terms of health is an important factor likely to influence psychological and endocrinal responses to stress (28, 29). Self-reported health is a rather valid indicator of one's health status, and previous research has shown an association between self-reported health and biophysiological stress markers (30–32) although there are also studies that do not find such an association (33). On an *intra*-individual daily basis, Dahlgren et al (34) found poor self-reported health to be associated with higher evening cortisol levels and lower morning cortisol levels the following day. This finding is especially important for our study as it also reported *intra*-individual analyses and, in addition, replicated the pattern described in the meta-analysis by Miller et

al (23) regarding lower cortisol levels in the morning but higher levels in the evening. In part, such changes may be directly due to biological processes; in addition, however, psychological processes are likely to be important. Specifically, good health can be regarded as an intra-personal resource (20, 35), which may mitigate responses in at least two ways. When one feels less healthy than usual, one may (i) react to stressors such as illegitimate demands with a stronger appraisal in terms of stressfulness (“...that’s the last thing I need now”), and (ii) have fewer coping resources available (eg, in terms of being able to regulate one’s emotions, confront one’s supervisor in a constructive way, etc). As a result, the reaction to stressors is likely to be stronger compared to times when one feels fit and healthy.

Based on these considerations, we expect the association between illegitimate tasks and cortisol to be stronger on occasions when subjective health is relatively poor (hypothesis 2).

Methods

Participants and procedure

The data for the current analyses are from a larger longitudinal study, containing three waves, with a time lag of six months between each wave (36). Participants worked in one of three organizations: a government administration, a publicly owned production site, and a publicly owned logistics organization. We recruited participants at promotional events in the respective organization. Altogether, 509 participants were eligible for the study; we have no exact figures about how many people participated in the promotional events, but the number was considerably lower than 509 – some did not attend, some were ill, some had to do “field work”. We received 176 completed questionnaires.

The present analyses refer to the male subsample of 107 employees. Data of three participants were excluded because they did not provide cortisol measures or because they were currently on medication. The resulting sample thus consisted of 104 participants, 102 of which also participated in the second and third wave. Participants worked in a variety of different jobs in administration, production (eg, metal, electronics), and logistics (transport); their age varied between 17–62 years [mean 41.21, standard deviation (SD) 11.67]. Twenty-six percent smoked (mean 5.15, SD 5.98 cigarettes). Four percent had completed primary education (9 years), 29% had completed an apprenticeship, 54% had completed college, and 14% had a university degree. Organizational tenure ranged from 0.03–39.5 years; average tenure was 10.35 years (SD 11.16). Most

of the participants (90%) were employed fulltime; the remaining 10% ranged between 50–95% of a fulltime equivalent. Fifty-one percent had 1–4 children, with a mean of 2.28 (SD 0.77).

At each of the three waves, participants completed a general questionnaire assessing working conditions, including illegitimate tasks, and subjective health status. Cortisol and health-related behavior (like smoking) were assessed on two workdays in each wave.

Measures

Illegitimate tasks. Illegitimate tasks were measured by the Bern Illegitimate Tasks Scale [BITS (11)]. The BITS consists of eight items (eg, “Do you have work tasks to take care of, which you believe should be done by someone else?”; “Do you have work tasks to take care of, which keep you wondering if they make sense at all?”). Participants rated each item on a 5-point Likert scale, ranging from 1 (*very rarely/never*) to 5 (*very often*). Cronbach’s alpha ranged from 0.85–0.86 across the three waves.

General health. Self-reported general health was measured by a single-item measure (“How would you describe your general state of health?”) on a 5-point Likert scale, ranging from 1 (*poor*) to 5 (*very good*). Across the three waves 13–19% stated ≤ 3 .

Salivary cortisol. Salivary cortisol levels were assessed at noon (before lunch) while people were at work; the assessment was linked to the routine of lunch break to increase compliance. Individuals were asked to refrain from eating, drinking (except water), brushing their teeth, and smoking one hour before measurement. In order to clarify questions and remind participants of the procedure, research assistants visited the participants at their workplace; they supervised the usage of cotton Salivette cylinders (Sarstedt, Sevelen, Switzerland), and immediately collected the samples to freeze them (below -20°C). Such a procedure is likely to be helpful in maintaining interest in the study and increasing compliance (37). Biochemical analysis of free cortisol in saliva was performed using a commercial enzyme-linked immunosorbent assay kit (DRG instruments GmbH, Marburg, Germany). All samples were completely processed by a fully automated open system (Nexgen Four, Adaltis, Freiburg, Germany). The analytical sensitivity of the assay is 0.331 nmol/l. All samples were analyzed in duplicates. The mean coefficient of intra-assay variance was $<5\%$ and the one for inter-assay variance was $<10\%$. Cortisol levels were averaged across the two days of the same wave ($r = 0.51$, $P < 0.05$). Salivary cortisol was within an appropriate range from 0.62–16.79 nmol/l. Since our data were skewed, we ran our analyses both

with the original data and with an algorithmic transformation. These analyses yielded a very similar pattern, leading to the same conclusions; we therefore report the analyses with the original data.

Control variables. We controlled for age and nicotine use because there are indications that they are related to salivary cortisol response (24). Nicotine consumption was assessed as the number of cigarettes or cigars smoked on the respective day prior to cortisol measurement. Furthermore, we controlled for wave-specific job stressors, specifically for social stressors with colleagues and work interruptions. Social stressors refer to tensions and conflict at work, which implies a high risk of social-evaluative threat; interruptions are typically non-controllable events (38). As social-evaluative threat and uncontrollability have been found to reliably predict increases in the cortisol response (26), we controlled for these two stressors in order to be sure that illegitimate tasks are able to predict the cortisol response over and above these stressors.

Social stressors with colleagues refer to negative interactions with colleagues and were measured with a shortened version of a social stressor scale (39), containing five items (eg, “With some colleagues one often quarrels”), using a 5-point Likert scale that ranged from 1 (*strongly disagree*) to 5 (*strongly agree*). Cronbach’s alpha ranged from 0.78–0.79. Work interruptions were measured by four items (eg, “How often are you interrupted by other colleagues at work?”) based on the Instrument for Stress Oriented Task Analysis (ISTA) (40). The items require a response on a 5-point scale that ranged from 1 (very seldom / never) to 5 (very often). Cronbach’s alpha ranged from 0.72–0.79.

Additionally, we controlled for the general level (ie, mean across waves) of perceived health and illegitimate tasks as well as for emotional stability at the beginning of the study [assessed by 6 items from Ostendorf’s 9-item adjective list (41), which have been shown to be psychometrically adequate by Schallberger & Venetz (42); Cronbach’s alpha was 0.78].

Statistical analysis

Illegitimate tasks, perceived health, and cortisol response were measured three times per person (level 1) and, thus, are nested within persons (level 2) (43). Therefore, we analyzed our data with a random hierarchical linear modeling approach [HLM, version 6.08 (44)], using the restricted maximum-likelihood procedure. Except for nicotine, we centered all level 1 predictors at the participant’s mean (“group mean centering”), which implies that the between-person variance for the particular variables is removed (45). Thus, significant coefficients for those variables reflect the effect of participants being

high or low relative to their own mean for that variable across the three waves (46).

Nicotine consumption was used as a control variable on level 1, reflecting the level of smoking at the particular measurement occasion; on level 2, we controlled for age, emotional stability plus the general level (ie, mean across waves) of perceived health and illegitimate tasks. Social stressors and work interruptions were controlled for on both levels. To confirm hypothesis 1, there should be a significant main effect of illegitimate tasks on salivary cortisol release. To confirm hypothesis 2, the interaction term had to be significant, and the pattern of the simple slopes had to match expectations. We calculated simple slope tests using an online tool by Preacher, Curran and Bauer (47).

Results

Descriptive results

Descriptive statistics are presented in table 1. All stressors were significantly correlated on the intra-individual level. To analyze whether participants’ cortisol release differed across the three waves, we calculated a null model, which yielded estimates of 0.34 for level 2 variance (between persons) and 0.66 for level 1 variance (within persons). Thus, 66% of the variance in salivary cortisol was attributable to within-person variance, indicating that examining intra-individual fluctuations by way of multilevel modeling was appropriate.

Testing of hypotheses

Results of the multilevel analyses are displayed in table 2. In model 1, we examined the effect of illegitimate tasks at level 1 (ie, wave-specific), controlling for social stressors with colleagues and interruptions at both levels, age, emotional stability and average level of illegitimate tasks at level 2, and nicotine as well as time of measurement (dummy coded) at level 1. No main effects of illegitimate tasks emerged on an intra-individual ($b=0.25$, $P>0.05$) or on an inter-individual ($b=0.21$, $P>0.05$) level, disconfirming hypothesis 1.

In model 2, we additionally entered perceived health, both in terms of average across waves (level 2) and in terms of wave-specific values (level 1); no main effect emerged.

In model 3, we added the interaction term between perceived health and illegitimate tasks at level 1. In line with hypothesis 2, there was a significant interaction between illegitimate tasks and perceived health ($b=2.91$, $P<0.01$). Model 3 showed a significant improvement over model 2 (difference of $-2 * \log=9.36$, $df=2$, $P<0.01$).

Table 1. Means, standard deviations (SD), minimal (Min) as well as maximal (Max) values over three waves, and zero-order correlations of the study variables. Correlations below the diagonal reflect the between-person associations of the averaged level 2 variables (person; N=104). Correlations above the diagonal reflect the within-person associations of the level-1 variables (measurement; N≤312). All self-report variables have a possible range from 1–5 with high values indicating more of the respective construct.

^a P<0.05 (2-tailed).

According to simple slope tests, illegitimate tasks were positively related to increased cortisol release when wave-specific self-reported health was relatively poor ($b=1.43$, $t=2.67$, $P<0.01$) but not when it was medium ($b=0.35$, $t=0.86$, $P=0.39$) or high ($b=-0.72$, $t=1.16$, $P=0.25$). This pattern is in line with hypothesis 2 (see figure 1). In line with statistical tradition (48), we chose values 1 SD below and above the group-centered sample mean, which approximately correspond to the 15th and 85th percentile. These results are independent of the average level of perceived health and illegitimate tasks, emotional stability, and the effects of work interruptions and social stressors. Social stressors showed no effect on either level. Work interruptions showed no effect on level 2, but did show a wave-specific effect (level 1), with higher levels of work interruptions resulting in higher salivary cortisol concentrations ($b=0.86$, $P<0.05$). No main effects of

self-reported general health emerged between ($b=0.36$, $P>0.05$) or within ($b=0.09$, $P>0.05$) persons.

Discussion

We proposed that illegitimate tasks trigger physiological stress-responses and are thus positively related to salivary cortisol. Moreover, based on the Allostatic Load model (28, 29) and general resource models [eg, the Conservation of Resources (COR) model (20); the Reserve Capacity model (35)], we proposed a moderating role of self-reported health, in that the association between illegitimate tasks and cortisol should be stronger for participants in times of relatively poor, as compared to good, health. There was no main effect of

Figure 1. Interaction between illegitimate tasks and health predicting cortisol at workday. [SD=standard deviation]

illegitimate tasks; however, the proposed interaction did emerge: Illegitimate tasks predicted cortisol only in waves in which participants rated their health comparatively low. Such a finding is not uncommon in occupational stress research. When people have high resources, they may better be able to cope with stressors or be less inclined to appraise them as highly stressful in the first place (27). Under such circumstances, main effects are to be expected only when stressors are rather intense, which is not the case in our study (cf. the relatively low means for illegitimate tasks). In line with this reasoning, many studies have found the effects of stressors to be qualified by resources, both external [eg, social support (49) and internal (eg, self-esteem (50, 51)]. The current study is the first one to show such effects for illegitimate tasks as a stressor and for perceived health as vulnerability factor.

Several features of our study are likely to have contributed to the finding of increased levels of cortisol, given that research in the field has yielded rather inconsistent results, with some studies finding elevated, but others reduced cortisol levels (23). Stress is typically associated with elevated cortisol levels in proximal or ongoing situations, such as daily experiences or, in our case, measurement occasions (23). Furthermore, higher levels of cortisol are to be expected later in the day, as compared to the morning, and when the stressors involved imply a threat to the self. Finally, intra-individual measures are associated with elevated cortisol levels more often than inter-individual ones (25). We measured cortisol at noon, related them to a stressor that constitutes a threat to the self, and analyzed our data intra-individually.

Feeling healthy may be a rather valid proxy of allostatic load; it has been associated with biophysiological stress markers (30–32, 34) and has been shown to predict mortality (52). If people feel less healthy, they may appraise situations as more stressful and their cop-

ing abilities may be impaired. This study is the first to show such effects for illegitimate tasks, and the effect persisted when controlling for inter-individual differences in illegitimate tasks and health (level 2) and for social stressors and interruptions at both levels.

These findings have important theoretical and practical implications. The biochemical stress marker cortisol demonstrated meaningful associations with illegitimate tasks under conditions of relatively poor health when both illegitimate tasks and health were assessed by self-report; this is important in light of criticisms that self-report measures are low in validity – a criticism that may be overstated (16, 53). Furthermore, our results support the assumption that the individual response to a potentially stressful situation depends on a person's current state of health. Note, however, that our results refer not to a population of patients but to working people who are, in general, comparatively healthy. “Relatively poor health” therefore still implies rather good health. The mean of perceived health was 4.15 on a scale ranging from 1–5; its SD was 0.68, implying that people with relatively poor health (figure 1) had a value of 3.47. Health can be considered an important individual resource (20); from this point of view, our results point to the importance of resources available for coping with stressful situations, and they suggest that – of these resources – health should receive more attention. For instance, interventions that improve health (through job and organization design, and/or health behavior) are likely to improve resilience to stress. It is conceivable that the physiological stress reaction impairs self-reported health and that health, at the same time, leads to an altered stress reaction. Finally, our study adds to existing knowledge through its focus on intra-individual analyses, since we did not focus on differences between individuals. Rather, our results imply that the *same individuals* have higher cortisol values during more stressful times (as indicated by illegitimate tasks) than during less stressful times, and only if their perceived health is relatively poor (as compared to their estimation of their health on average).

There are several limitations to our study. First, our sample size was rather small, which implies limited power and therefore an extended risk to miss a significant effect. Furthermore, the effects are not very large; converting the difference in predicted cortisol levels between participants with a high (versus low) level of illegitimate tasks into Cohen's *d* statistic yields a value of 0.32. That the effects are not stronger may be due to the fact that our participants were rather healthy and that we assessed cortisol assessment only once per day, at a time where the proposed increase is likely to have started, rather than in the evening, when it is likely to be more pronounced. Further research should investigate short-term effects of illegitimate tasks on cortisol release

using several measurements across the day and employ a longer time range (eg, several years) in order to capture cumulative effects. Also, our measure of the stress response was occasion-specific (ie, the average of two days during each wave of measurement); by contrast, the wording of the illegitimate tasks measure did not refer to the current wave of measurement but to illegitimate tasks in general, thus creating a discrepancy in the time frames, which may have weakened differences between waves in illegitimate tasks and, thus, associations with occasion-specific cortisol values. Note, however, that our respondents knew that there would be three waves, and the differences in illegitimate tasks between the waves (correlations for illegitimate tasks across the three waves ranged from $r=0.54-0.71$, and 37% of the total variance in illegitimate tasks is due to changes within participants across waves) suggest they took changes in their work situation between waves into account. Nevertheless, referring more specifically to the time preceding each measurement occasion (eg, "Did you *lately* have work tasks to take care of..." instead of "Do you...") might have yielded stronger differences in illegitimate tasks and potentially stronger associations with cortisol.

Third, we only investigated male employees due to the fact that cortisol is highly sex-specific and depends on the menstrual cycle and oral contraceptive usage among females [(21, 24, 25) but see (54)]. Therefore, conclusions can only be drawn for men. In addition, because our response rate was not very high, we cannot eliminate the possibility of a sampling bias (55). Furthermore, we did not register the time of sampling and therefore have no data on compliance with regard to timing. Given the considerable circadian variation in cortisol, our results might reflect timing rather than work stress or subjective health. Having information on the exact time of saliva sampling would have enabled us to include it in the statistical analysis (25, 54), possibly leading to clearer effects. Note, however, that research assistants were present at the site, reminding participants of the saliva sampling procedure and collecting the saliva samples personally; this procedure did ensure that the sampling times were not too far off the intended time. Finally, since illegitimate tasks are a relatively new stressor concept, the amount of research conducted up to now is limited (12, 13), so further replications of our findings are necessary; future studies should consider additional stress-related outcomes, potential mediating mechanisms, and individual differences.

This study adds to the evidence concerning the HPA stress-response and enhances knowledge regarding illegitimate tasks. Our results indicate that the perception of illegitimate tasks increases cortisol release in times of relatively impaired health. In terms of practical implications, these findings underline the importance of preventing stressful situations in general, and of

being sensitive to the potential illegitimacy of task assignments in particular, especially under conditions of relatively poor health. Considering the current health status of individuals may help to prevent loss spirals that are characterized by increased undermining of personal resources (such as health), which, in turn, may induce an augmented reactivity to stressful conditions. Thus, illegitimate tasks should be avoided, especially if health is already relatively poor.

Acknowledgement

The Swiss National Science Foundation supported part of this research with a grant [SNF 2005(100011-105538)] to Norbert K Semmer. The authors are associated with the Swiss National Centre of Competence in Research (NCCR) on "Affective Sciences" (director: K Scherer). Laurenz L Meier is now at the University of South Florida, Tampa, USA.
